Editor's Summary

Turning the Tables on Cholesterol

A big push in disease research is to identify biochemical markers (biomarkers) in the blood that are early indicators of a disease that is already silently under way. By detecting the disease in its earliest stages, drugs and other therapeutic interventions have the best chance of halting or reversing the course of the disease before major tissue damage has been done. In a new study, Porter and colleagues set out to identify blood biomarkers for Niemann-Pick C1, a childhood neurological disease that is usually fatal.

Niemann-Pick C1 disease is caused by mutations in the NPC1 or NPC2 proteins that result in mishandling of cholesterol and lipids in the endolysosomal system of cells. This leads to aberrant deposition of free cholesterol in the central nervous system, the death of neurons, and increasing motor and intellectual impairment, usually resulting in death during adolescence. The early symptoms of the disease are often difficult to distinguish from other childhood diseases, and thus, intervention in the form of a drug such as miglustat often comes too late. This prompted Porter and coworkers to search for possible molecules in the blood that could be used for early diagnosis of the disease and also to monitor the effectiveness of new drugs. On the basis of reports that aberrantly deposited free cholesterol is associated with increased oxidative stress, these investigators reasoned that cholesterol oxidation products (oxysterols) might be the long-sought biomarkers for Niemann-Pick C1 disease.

Working in mice lacking the Npc1 gene, the researchers quickly identified two oxysterols that were markedly elevated in the plasma and tissues of the sick mice but not their healthy counterparts. Furthermore, the concentrations of these two oxysterols increased as the disease progressed. Moving into cats carrying an NPC1 mutation, which exhibit similar disease symptoms and progression as human patients, Porter and coworkers were able to decrease elevated concentrations of the two oxysterols and ameliorate disease symptoms by treating the animals with the experimental drug cyclodextrin. But could oxysterols be used as biomarkers in the human disease? The investigators demonstrated that the blood concentrations of two related oxysterol molecules were almost 10 times higher in Niemann-Pick C1 patients than in age-matched healthy controls or those with other diseases such as atherosclerosis or diabetes. Together, these compelling results suggest that the two oxysterol molecules are accurate diagnostic markers of early clinical disease and can be used not only to monitor disease progression but also to demonstrate drug efficacy. Free cholesterol may be at the root of Niemann-Pick C1 disease, but now, there is a way to turn the tables on cholesterol by using its oxidation products to diagnose and treat the disease in its earliest stages.

Niemann-Pick type C1 (NPC1) disease is a rare progressive neurodegenerative disorder characterized by accumulation of cholesterol in the endolysosomes. Previous studies implicating oxidative stress in NPC1 disease pathogenesis raised the possibility that nonenzymatic formation of cholesterol oxidation products could serve as disease biomarkers. We measured these metabolites in the plasma and tissues of the Npc1−/− mouse model and found several cholesterol oxidation products that were elevated in Npc1−/− mice, were detectable before the onset of symptoms, and were associated with disease progression. Nonenzymatically formed cholesterol oxidation products were similarly increased in the plasma of all human NPC1 subjects studied and delineated an oxysterol profile specific for NPC1 disease. This oxysterol profile also correlated with the age of disease onset and disease severity. We further show that the plasma oxysterol markers decreased in response to an established therapeutic intervention in the NPC1 feline model. These cholesterol oxidation products are robust blood-based biochemical markers for NPC1 disease that may prove transformative for diagnosis and treatment of this disorder, and as outcome measures to monitor response to therapy.

INTRODUCTION

Niemann-Pick type C1 (NPC1) disease is a rare, progressive neurodegenerative disorder with an estimated incidence in Western Europeans on the order of 1 in 120,000 to 150,000 (1). This number is almost certainly an underestimate because of the difficulty in establishing the diagnosis. About 95% of NPC cases are caused by mutations of the NPC1 gene, which is located on chromosome 18q11 (2); the remaining 5% are caused by mutations in the NPC2 gene, mapped to chromosome 14q24.3 (3). In patients with NPC1 disease, cholesterol and other lipids accumulate in the viscera and central nervous system (CNS) (4, 5). In early childhood, affected individuals typically exhibit ataxia and progressive impairment of motor and intellectual function, and they usually die in adolescence. A major barrier to delivery of effective treatment for NPC disease has been the lack of a noninvasive and inexpensive diagnostic test, thus leading to diagnostic delays of >4 years (6). The time to diagnosis is critical because early intervention is likely to yield the most benefit in this disease.

Mutations in the NPC1 and NPC2 genes profoundly affect the intracellular trafficking of cholesterol and, as a consequence, lead to accumulation of free cholesterol in late endosomal/lysosomal structures (4, 7). Several lines of evidence suggest that the lysosomal lipid accumulation in NPC disease is accompanied by cellular oxidative stress. In vitro studies show increased oxidative stress in cultured fibroblasts and neurons. NPC1-deficient fibroblasts show increased concentrations of reactive oxygen species (ROS) and lipid peroxidation and exhibit a gene expression profile indicative of oxidative stress (8, 9). Likewise, treatment of mouse cortical neurons with U18666A, a compound that induces an NPC cellular phenotype, leads to increased oxidative stress (10). In vivo studies similarly provide evidence of cellular and tissue oxidative stress in NPC1 disease. Murine Npc1−/− deficient macrophages show increased ROS and harbor signs of chronic oxidative damage (11), and in human NPC1 subjects antioxidant capacity in serum is decreased (12). Concomitant with elevated ROS, there is a marked increase in cholesterol oxidation products, which are formed nonenzymatically after attack of cholesterol by oxygen free radicals (11). These cholesterol oxidation products, or oxysterols, are uniformly elevated in multiple tissues and plasma of Npc mutant mice (Npc1−/−) (11, 13).

We hypothesized that the elevated cholesterol oxidation products in the tissues of Npc1−/− mice are a reflection of the unique intersection of oxidative stress and excess intracellular free cholesterol that is the hallmark of NPC1 disease. Here, to test whether concentrations of circulating oxysterols might serve as markers for NPC1 disease, we analyzed plasma and tissue samples from Npc1−/− mice over their 11-week life span. Furthermore, oxysterols that associate with disease in the murine model were examined in plasma and cerebrospinal fluid (CSF) from NPC1 and age-matched control subjects. We found that several cholesterol oxidation products were markedly elevated in the plasma...
of NPC1 subjects, but not in other neurodegenerative or lysosomal storage diseases, and correlated with severity and age of onset of disease.

RESULTS

Cholesterol oxidation products in plasma and tissues of Npc1-deficient mice

Previous demonstration of increased oxidative stress and elevated cholesterol oxidation products in the tissues of Npc1-deficient mice raised the possibility that circulating, nonenzymatically generated oxysterols might serve as markers for NPC disease. To test this possibility, we monitored plasma oxysterol concentrations over the life span of the BALB/c NPCemb (Npc1−/−) mouse, a naturally occurring murine model that harbors a retroposon insertion in the Npc1 gene (14). We measured oxysterol species formed exclusively by nonenzymic reactions [cholestanol, 3β,5α,6β-trioli (3β,5α,6β-trioli), 7β-hydroxycholesterol (7β-HC), and 7-ketocholesterol (7-KC)] and species for which there is evidence for both enzymatic and nonenzymatic synthesis in vivo [4β-hydroxycholesterol (4β-HC), 7α-hydroxycholesterol (7α-HC), and 25-hydroxycholesterol (25-HC)] (Fig. 1). In contrast to control wild-type littermates, Npc1−/− mice failed to appropriately gain weight and started to lose weight by 7 to 8 weeks of age (Fig. 2A). Npc1−/− mice exhibited decreased coordination, as evidenced by rotarod testing, beginning at 7 weeks of age (Fig. 2B), and life span was markedly shortened, with a mean survival of 78 days (Fig. 2C) (15). In pooled plasma samples, elevations in 25-HC and 3β,5α,6β-trioli were present at virtually all ages in Npc1−/− mice as compared to control mice (Fig. 2, D and E). By contrast, elevations in 7-KC, 4β-HC, 7α-HC, and 7β-HC were most prominent after 7 weeks of age, when the Npc1−/− mice began losing weight and were overtly symptomatic (Fig. 2, F to I). (These oxygenated cholesterol species represent, for the most part, nonenzymatically formed oxidation products, although 4β-HC, 7α-HC, and 25-HC can also be generated enzymatically.) Nonetheless, a subset of cholesterol oxidation products (25-HC, 3β,5α,6β-trioli, 7-KC, 7α-HC, and 7β-HC) were all increased in the plasma of the 4-week Npc1−/− mice, an age that predates onset of neurological symptoms, and all of the oxysterols examined were significantly elevated in 8- to 10-week Npc1−/− mice.

The elevated plasma oxysterols in the Npc1−/− mice were accompanied by altered tissue oxysterol concentrations. In livers of 9-week-old Npc1−/− mice, there was marked accumulation (3.4 to 8.9 times increase compared to wild type) of multiple nonenzymatically formed cholesterol oxidation products (4β-HC, 7β-HC, 5β,6β-epoxycholesterol, 5α,6α-epoxycholesterol, 7-KC, 7α-HC, and 3β,5α,6β-trioli) (Fig. 3, A and B). Elevated 3β,5α,6β-trioli concentrations, in contrast to other oxidized cholesterol species, were also evident in whole brain (increased 4.3 times, P < 0.001) and in the cerebellum, a region of the brain profoundly affected by the neurodegenerative disease process in the Npc1−/− mice (Fig. 3, C and D). An age-dependent, significant elevation of 3β,5α,6β-trioli in the cerebellum was detected beginning at 4 weeks in asymptomatic Npc1−/− mice (Fig. 3D), consistent with the known cholesterol storage and asymptomatic neuroinflammatory changes that are evident as early as 9 days in the Npc1−/− mice (16). In contrast to the nonenzymatic cholesterol oxidation products, enzymatically formed 24(S)-hydroxycholesterol [24(S)-HC] concentrations were attenuated 35% (P < 0.001) in whole-brain tissue of the 9-week-old Npc1−/− mice compared to wild-type mice (Fig. 3E). Reduced formation of 24(S)-HC has been reported previously for Npc1−/− mice, as well as in human neurodegenerative diseases, and is thought to be due to dysfunction and/or loss of large neurons (17, 18). Despite the reduced 24(S)-HC production, 24(S)-HC concentrations were increased 2.8 times (P < 0.001) in the liver of the Npc1−/− mice (Fig. 3B). These elevated steady-state concentrations of 24(S)-HC were likely a manifestation of both the hepatocellular disease in the Npc1−/− mice and the central role of the liver in clearance of plasma oxysterols (19). Together, these findings raised the possibility that plasma concentrations of nonenzymatically generated oxysterols might aid in the diagnosis of human NPC1 disease and be informative with respect to disease progression.

Elevated cholesterol oxidation products in the plasma of human NPC1 subjects

To study the association of oxysterols with human NPC1 disease, we obtained plasma samples from human NPC1 subjects enrolled in an observational study at the U.S. National Institutes of Health (NIH). We initially performed a pilot study on plasma samples from 10 NPC subjects, in which we used isotope dilution gas chromatography–mass spectrometry (GC-MS) to monitor 22 distinct oxysterol species...
Fig. 2. Cholesterol oxidation products are elevated in the plasma of Npc1−/− mice. (A) Weight gain of wild-type (WT) and Npc1−/− mice. (B) Rotarod performance of WT and Npc1−/− mice. Error bars for WT mice are contained within the bars. (C) Kaplan-Meier survival analysis of WT and Npc1−/− mice. (D to I) 25-HC, 3β,5α,6β-triol, 7-KC, 4β-HC, 7α-HC, and 7β-HC plasma concentrations measured weekly in pooled plasma samples (n = 5 to 8 mice per group) obtained from WT and Npc1−/− mice. For 8- to 10-week time points, *P ≤ 0.05 for Npc1−/− versus WT control. In (D) to (H), the error bars represent the precision of replicate testing of pooled samples.
(table S1) known to be present in human plasma (20, 21). Comparison with previously reported reference values (21–23) allowed us to identify two species that were increased (3β,5α,6β-triol and 7-KC) and one that was decreased (24-HC) in the NPC1 plasma samples. On the basis of these findings, we measured these three oxysterol species in plasma samples in a validation cohort of 25 fasting NPC1 subjects (1 to 51 years; mean age, 11.3 years), 23 obligate heterozygotes (parents of NPC1 subjects) or known sibling carriers. Control subjects were matched for age, but not for gender, because there were no differences in oxysterol profiles between male and female controls. We found that the two cholesterol oxidation products, 3β,5α,6β-triol (control mean, 20.1; range, 7.9 to 42.9; NPC1 mean, 193.6; range, 82.9 to 328.8) and 7-KC (control mean, 77.4; range, 39.4 to 338.8; NPC1 mean, 725.9; range, 311.6 to 1294.1), were markedly elevated in NPC1 subjects compared to age-matched controls (P < 0.001, using Bonferroni posttest correction for multiple comparisons) (Fig. 4, A and B). Although the range of values overlapped with controls, these oxidation products were also elevated in the heterozygotes. Even excluding the single heterozygote subject with marked elevation of 7-KC, mean 7-KC and 3β,5α,6β-triol concentrations in the heterozygotes were increased 1.8 and 1.9 times, respectively, over control subjects (7-KC, P < 0.05; 3β,5α,6β-triol, P < 0.001) (Fig. 4C). When both 7-KC and 3β,5α,6β-triol concentrations were plotted for individual subjects, these oxysterol species were sufficient to permit complete discrimination of NPC1 subjects from controls and heterozygotes (Fig. 4D). The plasma 3β,5α,6β-triol and 7-KC concentrations were highly correlated (r = 0.9), indicating that generation of these oxidation products in vivo likely involves a common process. This result is consistent with our hypothesis that increased oxysterols in NPC1 subjects reflect the unique intersection of increased intracellular free cholesterol and increased oxidative stress. Receiver-operator curve (ROC) analysis demonstrated that the area under the curve for 3β,5α,6β-triol was 1.0 and for 7-KC was 0.9984, reflecting the high sensitivity and specificity afforded by the markers.

The marked elevation in circulating cholesterol oxidation products is consistent with known increases in the free cholesterol precursor and oxidant tone in NPC1-deficient tissues (8, 9, 11–13). The cholesterol oxidation products were unlikely to have been formed in the circulation or subsequent to blood collection, because no significant association was found between plasma cholesterol and oxidation products (fig. S1, A and B). Compared to controls, plasma 3β,5α,6β-triol/cholesterol and 7-KC/cholesterol ratios in NPC1 subjects were elevated 9.9 and 10.6 times, respectively, thus demonstrating that enhanced oxidant stress, rather than an increase in oxidation products resulting from an increase in precursor molecules, was responsible for the elevated plasma oxysterols (fig. S1, C and D). Even among familial hypercholesterolemia subjects with total plasma cholesterol of >300

![Fig. 3. Accumulation of nonenzymatic cholesterol oxidation products in Npc1<sup>−/−</sup> mouse tissues. (A and B) Oxysterol concentrations in livers of 9-week-old WT and Npc1<sup>−/−</sup> mice. mg/dl, the plasma 3β,5α,6β-trioli and 7-KC concentrations were within the normal range (fig. S1E). Furthermore, the lack of association between plasma cholesterol oxidation products and serum Trolox equivalent antioxidant capacity (TEAC), a measure of total antioxidant capacity, demonstrates that elevated serum concentrations of 3β,5α,6β-trioli and 7-KC are independent of the oxidative environment in the plasma (fig. S1F).

In contrast to the elevated nonenzymatic oxidation products, mean plasma 24(S)-HC, an enzymatically formed oxysterol, was lower in NPC1 subjects than in controls (control mean, 97.7; range, 34.8 to 234.1; NPC1 mean, 75.1; range, 19.3 to 209.3) (Fig. 4E). In light of the age-dependent decline in circulating 24(S)-HC concentrations, plasma 24(S)-HC values were further analyzed. We found that 24(S)-HC plasma concentrations were significantly reduced in the NPC1 subjects compared to age-matched controls (Fig. 4E; P < 0.005, using Bonferroni posttest correction for multiple comparisons). In humans, 24(S)-HC is formed almost exclusively in the CNS, and its concentrations in plasma reflect the balance between cerebral production and hepatic clearance (17). Therefore, neurodegenerative changes in the NPC1 subjects would be expected to yield lower plasma 24(S)-HC concentrations, similar to those reported for subjects with Alzheimer’s disease or neuroinflammation (17). The considerable overlap in plasma 24(S)-HC concentrations between the groups, however, suggests that by itself plasma 24(S)-HC is not a sufficiently robust marker to permit discrimination between NPC1 and unaffected individuals.

To examine the stability of the oxysterol measurements in the plasma samples, we measured the oxysterols under different processing conditions. Routine samples were collected in EDTA and butylated hydroxytoluene (BHT)-containing tubes and immediately centrifuged, and the plasma was removed and stored at −80°C. All processing of archived samples was performed under argon, which prevented formation of adventitious cholesterol oxidation products. Stability of the oxysterols was determined by collecting the plasma samples in the presence or absence of BHT and by processing after overnight storage either at 4°C or at room temperature. 7-KC demonstrated remarkable stability and was unaffected by the absence of BHT, processing delay, or storage temperature (Fig. 4F). Detection of the 3β,5α,6β-trioli species was similarly unaffected by altered processing of the plasma samples. We observed, however, up to a 25% increase in 3β,5α,6β-trioli concentrations after a processing delay and storage at room temperature (P < 0.05), possibly reflecting conversion of precursor oxidation products, 5α,6α-epoxycholesterol and...
5β,6β-epoxycholesterol, to the trihydroxylated 3β,5α,6β-triol species. On the other hand, oxysterol concentrations in plasma samples appear to be stable during storage at -80°C. Repeat 3β,5α,6β-triol and 7-KC determinations on samples stored at -80°C for up to 6 weeks showed a coefficient of variance of <10%. Furthermore, we can detect elevated 3β,5α,6β-triol and 7-KC concentrations in plasma samples from NPC1 subjects that have been archived for up to 10 years. We also investigated whether 7-KC or 3β,5α,6β-triol demonstrated diurnal variation. We found no evidence of a diurnal pattern for either 7-KC or 3β,5α,6β-triol, although the nonfasting oxysterol determinations deviated from fasting concentrations by up to 16% and 23% for 7-KC and 3β,5α,6β-triol, respectively (Fig. 4, G and H). Nonetheless, the observed intra-subject variation for the oxysterol measurements was small compared to the differences between NPC1 and control values.

Because the plasma cholesterol oxidation products are manifestations of tissue oxidative stress, we explored whether the clinical presentation of disease in the NPC1 subjects might reflect the degree of cellular oxidative stress and, ultimately, the severity of the intracellular cholesterol trafficking defect. Using skin fibroblasts obtained from study subjects, we measured free cholesterol concentrations, as well as low-density lipoprotein (LDL)–stimulated cholesterol esterification. Impaired delivery of LDL-derived cholesterol to the endoplasmic reticulum (ER) for reesterification is a hallmark of the NPC1 cellular lesion. Free cholesterol concentrations were increased 3.6 to 10.0 times in the NPC1 fibroblasts compared to wild-type fibroblasts. Consistent with this finding, LDL-stimulated cholesterol esterification was markedly reduced in the fibroblasts of most NPC1 subjects and, not unexpectedly, was strongly associated with cellular free cholesterol ($r = -0.64; P < 0.01$) (Fig. S2). However, the association of these cellular phenotypes with the oxysterol biomarkers was relatively modest ($r = 0.22$ for 7-KC and $r = 0.25$ for 3β,5α,6β-triol), indicating that the amount of circulating oxysterol appears to be determined only in part by the severity of the NPC1 cellular lesion.

### Specificity of plasma oxysterols for NPC disease
To evaluate the specificity of the plasma oxysterol profile for NPC1 disease, we measured oxysterols in subjects with type 2 diabetes and in subjects with coronary artery disease (CAD), two common conditions that are associated with oxidative stress. In diabetics, plasma 3β,5α,6β-triol and 7-KC concentrations were increased only 1.4 and 1.2 times, respectively, compared with controls matched for age, gender, smoking status, and statin usage (Fig. 5). In subjects with angiographically proven CAD, plasma 3β,5α,6β-triol and 7-KC concentrations were increased 1.4 and 1.5 times, respectively, compared with matched controls. By contrast, these biomarkers were elevated 9.6 and 9.3 times, respectively, in the NPC1 subjects. Moreover, none of the diabetic or CAD subjects exhibited oxysterol concentrations that overlapped with the range of values for the NPC1 subjects.

We further examined the circulating oxysterol concentrations in several other lysosomal storage diseases [infantile neuronal ceroid lipofuscinosis (INCL), GM-1 gangliosidosis, GM-2 gangliosidosis, and Gaucher disease (GD)] that have similar clinical presentations (for example, hepatosplenomegaly and cognitive impairment) to NPC1 disease and for which a diagnostic blood-based test that differentiated NPC1 disease from other lysosomal storage diseases would be extremely useful. Plasma 3β,5α,6β-triol and 7-KC concentrations were significantly elevated in NPC1 subjects (Fig. 6, A and B). 3β,5α,6β-Triol concentrations, and to a lesser extent 7-KC, were able to differentiate NPC1 subjects from subjects with other lysosomal storage diseases. Plasma 24(S)-HC concentrations were similar in subjects with NPC1 and other lysosomal storage diseases, with the exception of INCL subjects in which the 24(S)-HC was profoundly reduced (Fig. 6C), consistent with the widespread cortical atrophy that typifies this disorder.
CSF of either the NPC1 or the control subjects. This could reflect reduced 24(S)-HC synthesis or, more likely, conversion to oxidation products not detectable by the selective ion monitoring used in our study. Thus, NPC subjects demonstrate a distinct CSF oxysterol profile in which there is alteration of specific cholesterol oxidation products, consistent with the cholesterol oxidation signature found in the brain tissue of the Npc1<sup>−/−</sup> mice.

Correlation of oxysterol biomarkers with severity of human NPC1 disease

The wide range in 7-KC (311 to 1294 ng/ml) and 3β,5α,6β-triol (89 to 328 ng/ml) plasma concentrations within this phenotypically heterogeneous cohort of patients with NPC1 disease raised the possibility that the magnitude of the oxysterol biomarkers might be informative regarding disease severity. We found that the age of initial presentation of disease in the NPC1 subjects, which ranged from 1 week to 8 years, was significantly associated with plasma concentrations of both 7-KC (r = −0.41, P < 0.05) and 3β,5α,6β-triol (r = −0.40, P < 0.05) (Fig. 8, A and B). Furthermore, NPC1 disease severity, based on severity scale rank within the cohort (6), correlated significantly with concentrations of both 7-KC (r = 0.39, P < 0.05) and 3β,5α,6β-triol (r = 0.39, P < 0.05) (Fig. 8, C and D). An even more robust association emerged between disease severity and an oxysterol index that incorporates either 7-KC or 3β,5α,6β-triol concentrations, which vary directly with severity, and age-corrected 24(S)-HC concentrations, which vary inversely with disease severity (for 7-KC, r = 0.66, P < 0.001; for 3β,5α,6β-triol, r = 0.60, P < 0.001) (Fig. 8, E and F). Together, these findings indicate that the oxysterol biomarkers may be informative with respect to the clinical course of disease.

Decreased circulating oxysterol biomarkers in response to therapy

To assess whether 7-KC and 3β,5α,6β-triol might serve as markers of therapeutic efficacy in NPC1 disease, we measured the oxysterols in a feline model of NPC1 disease that is well documented and known to resemble the juvenile-onset form of the disease in children (5, 24). In the serum of NPC1 cats, 7-KC and 3β,5α,6β-triol concentrations were increased 1.3 and 9.4 times compared to wild-type littermates (Fig. 9) Notably, the relative increase in 3β,5α,6β-triol concentration in the affected cats was identical to that observed in human NPC1 subjects. Serum samples were analyzed in 16- to 18-week NPC1 cats that were untreated or treated with a single dose of 2-hydroxypropyl-β-cyclodextrin (cyclodextrin; 4000 or 8000 mg/kg subcutaneously), which has been shown to prolong life span in both the NPC1 mouse and the feline models (25–28). Initiation of cyclodextrin treatment at 3 weeks led to amelioration of clinical neurological disease and significant reduction of 3β,5α,6β-triol and 7-KC concentrations in the serum of the cyclodextrin-treated cats (Fig. 9). These findings raise the possibility that oxysterol biomarkers may provide metrics to fol-
low efficacy of therapy and/or disease progression in human NPC1 subjects.

**DISCUSSION**

A major impediment to the development of effective treatments for NPC disease has been the lack of outcome measures to evaluate therapeutic efficacy in this cholesterol storage disorder. A number of recent in vitro and in vivo studies indicate the presence of increased oxidative stress in NPC1 disease (8–11, 13). On the basis of these studies, we explored the possibility that oxidative attack of the excess free cholesterol in these patients might lead to increased formation of cholesterol oxidation products, which could serve as disease biomarkers. Using the Npc1−/− mouse model, we identified cholesterol oxidation products that were elevated, in both tissues and plasma, and were associated with disease progression. Nonenzymatically formed cholesterol oxidation products were similarly increased in the plasma of human NPC1 subjects. The specific oxysterol species differed to some degree between humans and mice, and this may reflect inherent differences in sterol metabolism between the species. Measurement of plasma oxysterols allowed for sensitive and specific detection of NPC1 disease in mice and humans. Furthermore, plasma oxysterol concentrations were correlated with the severity and age of disease onset. In mice lacking the Npc1 gene, alterations in plasma oxysterols could be detected before the onset of clinical disease, and in NPC1 patients were evident when there were minimal to no neurological symptoms. These cholesterol oxidation products can serve as NPC1 disease–specific biochemical markers and may prove useful for early detection of NPC1 disease and for evaluation of therapeutics in clinical trials.

In vivo conversion of lipoprotein cholesterol to oxygenated cholesterol metabolites (oxysterols) occurs in all tissues through both enzymatic and nonenzymatic pathways (Fig. 1). Side-chain oxysterols, which are generated by oxidation of the isooctyl side chain of cholesterol, are biologically active and regulate acute sterol homeostatic responses via transcriptional and posttranslational mechanisms. These oxysterols, which include 24-, 25-, and 27-HC, are predominantly synthesized by cytochrome P450 enzymes that reside in the ER (for example, CYP46A1) and mitochondria (for example, CYP27A1). In contrast to side-chain oxysterols, steroid ring–modified oxysterols are principally generated nonenzymatically as a result of the susceptibility of the C-5,6 double bond and the C-7 vinylic methylene group of cholesterol to radical and nonradical oxidation reactions (29, 30). The major products of free radical–based oxidation of cholesterol include 7α-HC, 7β-HC, 7-KC, and the epimeric 5/6-epoxides (30). The latter species are abundant in oxidized

**Fig. 8.** Correlation of plasma oxysterol concentrations with age of NPC1 disease onset and disease severity. (A and B) Plasma 7-KC (A) and 3β,5α,6β-triol (B) concentrations correlated with age of disease onset in NPC1 subjects. For 7-KC, $r = -0.40$, $P < 0.05$; for 3β,5α,6β-triol, $r = -0.41$, $P < 0.05$. (C and D) Plasma 7-KC (C) and 3β,5α,6β-triol (D) concentrations correlated with disease severity rank in NPC1 subjects. For (C) to (E), the severity rank increases with clinical severity of disease. For 7-KC, $r = 0.39$, $P < 0.05$; for 3β,5α,6β-triol, $r = 0.39$, $P < 0.05$. (E and F) Correlation of ratio of plasma 7-KC (E) and 3β,5α,6β-triol (F) to age-corrected 24(S)-HC values with disease severity rank in NPC1 subjects. For 7-KC, $r = 0.66$, $P < 0.001$; for 3β,5α,6β-triol, $r = 0.60$, $P < 0.001$. 

---

LDL and in macrophages, and serve as substrates for the ubiquitous cholesterol epoxide hydrolase to yield 3β,5α,6β-triol (29, 31).

In vivo, multiple mechanisms are likely responsible for the generation of the free radicals that cause cholesterol oxidation, including iron-catalyzed reduction of H$_2$O$_2$ to superoxide or peroxynitrite (30). Superoxide anions interact with polyunsaturated fatty acyl chains in membranes to produce hydroperoxy lipid radicals that are required for formation of both 5,6-epoxysterols, the precursor to 3α,5β-dihydroxycholesterol, and 7-KC. In cells, the enzyme complex primarily responsible for generation of superoxide anions is the NADPH oxidase (reduced form of nicotinamide adenine dinucleotide phosphate) oxidase complex (32). This complex is activated by lactosylceramide enrichment of cell surface glycosphingolipid signaling domains (33, 34). In light of the marked accumulation of lactosylceramide in multiple tissues in NPC1 subjects (35), it seems plausible that the well-characterized cholesterol-induced perturbations of glycosphingolipid metabolism in NPC disease may contribute to ROS production through activation of NADPH oxidase.

Nonenzymatically formed oxysterols have been reported to be elevated in human diseases associated with oxidative stress. The major circulating cholesterol oxidation products—7α-HC, 7β-HC, 7-KC, and the epimeric 5,6-epoxides—have been shown to be elevated in the plasma of diabetic (36, 37) and obese subjects (38). Increased 7α-HC and 7β-HC concentrations were also found in subjects with normal plasma cholesterol and atherosclerotic disease (39). In diabetes and atherosclerosis, however, the relatively modest increase in circulating oxysterol concentrations (increased ~1.3 times) and considerable overlap between subject groups suggests that these metabolites may have limited utility as disease markers in these disorders. By contrast, mean plasma 7-KC and 3β,5α,6β-triol concentrations were increased 9.4 and 9.6 times, respectively, in the NPC1 subjects, and, when used in combination, these species allowed discrimination of NPC1 subjects from age-matched controls with 100% sensitivity and specificity. These plasma oxysterols are stable, can be reproducibly measured, and exhibit only modest within-subject variation, which augurs well for their use as clinical biomarkers for NPC1 disease. In addition to their utility in monitoring disease, nonenzymatically formed oxysterols may also contribute to disease pathogenesis through their ability to promote apoptosis or to stimulate inflammation (29, 40, 41). In particular, the 3β,5α,6β-triol species, which is elevated in the cerebellar tissue of Npc1$^{-/-}$ mice and in the CSF of human NPC1 subjects, has been reported to be cytotoxic and promote mitochondrial dysfunction (42).

In contrast to the marked elevation of cholesterol oxidation products, NPC1 disease was associated with reduced enzymatic formation of 24(S)-HC in the brain tissue of Npc1$^{-/-}$ mice. Because the rate of 24(S)-HC flux into the plasma reflects cholesterol turnover in metabolically active neurons in the CNS, reduced plasma 24(S)-HC concentrations in NPC1 may result from the loss of sterol 24-hydroxylase–expressing neuronal populations (for example, Purkinje cells). Reduced plasma 24(S)-HC concentrations have previously been reported in Alzheimer’s disease and in the setting of neuroinflammation (17). Moreover, the profound reduction in 24(S)-HC concentrations in the subjects with infantile neuronal lipofuscinosis (Fig. 6C), a lysosomal storage disease characterized by rapidly progressive brain atrophy, provides further support for 24(S)-HC as a general marker of neurodegeneration. Concomitant with reduced 24(S)-HC, we detected increased formation of 3β,5α,6β-triol in the brain tissue of the Npc1$^{-/-}$ mice. Thus, nonenzymatic cholesterol oxidation may explain the augmented CYP46A1-independent sterol excretion in the Npc1$^{-/-}$ mice (18).

Barriers to the development of more effective treatments for NPC disease have been its rare disease status and the lack of outcome measures to evaluate efficacy of therapy in clinical trials. The finding that 7-KC and 3β,5α,6β-triol markers were significantly lowered by treatment with cyclodextrin, a compound that prolongs survival in NPC1 animal models (25–28) and is being administered to human NPC1 subjects through a Food and Drug Administration (FDA)–approved single-patient investigational new drug application, provides a biochemical-based, surrogate endpoint that could facilitate clinical evaluation of cyclodextrin and other emerging therapeutics.

Circulating oxysterols may additionally serve as metrics for monitoring the clinical course of NPC1 disease. Although correlation of the oxysterol markers with disease progression is limited by the pleiotropic nature of the disease (for example, multiple disease genotypes) and small sample size in our study, we were able to demonstrate significant correlations between plasma concentrations of 7-KC and 3β,5α,6β-triol and age of disease onset and severity. Moreover, plasma oxysterol concentrations expressed as the ratio of cholesterol oxidation products to age-normalized 24(S)-HC were even more informative than individual oxysterols in predicting disease severity. The higher predictive power of this oxysterol index may reflect inclusion in the index of markers of both oxidative stress and neuronal damage/loss, processes that are central to the pathogenesis of NPC1 disease. Given the variability in disease progression, even among siblings with a common genotype, these oxysterol biomarkers may prove most useful when applied longitudinally in individual NPC1 subjects.

An unexpected finding was the near doubling in plasma 7-KC and 3β,5α,6β-triol among the NPC1 heterozygotes, because humans with NPC1 haploinsufficiency have not been reported to develop clinical symptoms of NPC1 disease. On the other hand, Purkinje cell loss and enhanced phosphorylation of tau is present in aged Npc1$^{-/-}$ mice, and in a feline NPC1 model, heterozygotic cats exhibit intermediate biochemical phenotypes for cholesterol esterification and lipid accumulation in the liver (43, 44). Moreover, abnormal filipin staining patterns have been reported in skin fibroblasts from obligate human heterozygotes, indicating accumulation of lysosomal free cholesterol, which may serve as a substrate for nonenzymatic formation of cholesterol oxidation products (45). Because of the wide phenotypic

**Fig. 9.** Circulating oxysterol biomarkers are decreased in response to cyclodextrin therapy. (A and B) Serum 7-KC (A) and 3β,5α,6β-triol (B) concentrations were measured in untreated WT (4 to 16 weeks) and NPC1 (16 weeks) cats and in NPC1 cats (16 to 18 weeks) treated with a single subcutaneous injection of 4000 or 8000 mg/kg of cyclodextrin at 3 weeks ($n = 2$ to 4 per group). *$P \leq 0.05$ for cyclodextrin-treated versus untreated animals; **$P < 0.01$ for untreated NPC1 versus WT animals.
spectrum of NPC1 and the fact that a skin biopsy is necessary for biochemical diagnosis, NPC1 disease is likely underdiagnosed. Thus, the carrier frequency for NPC1 mutations is likely higher than the 0.6% predicted by a disease incidence of 1:120,000. If the increased circulating oxysterols are indicative of tissue oxidative stress, then human NPC1 heterozygotes, in whom the magnitude of the oxysterol elevation is comparable to those of diabetic and atherosclerotic subjects (36, 37, 39), may be at risk for neurodegeneration or other oxidative stress–related diseases. Thus, it is possible that therapeutic strategies under development for NPC1 subjects, such as antioxidant therapy to reduce ROS or small-molecule chaperones to increase NPC1 protein stability, may also reduce disease risk in heterozygotic subjects.

The availability of a simple, quantitative blood test for diagnosis of NPC disease would provide an unprecedented opportunity for early disease detection and the possibility of intervention in neurologically asymptomatic subjects. Specifically, a blood-based screening or diagnostic test would be applicable to infants presenting with cholestatic jaundice, in which the prevalence of NPC is as high as 8% (46); any infant or child with hepatomegaly or splenomegaly, in which there is suspected lipid storage disease; children with mild neurological deficits or learning disorders; and adolescents or adults with psychiatric disease and neurological symptoms (47). Clinical evidence is accumulating that miglustat, an amino sugar that inhibits the synthesis of glycosphingolipids, may slow neurological progression (48); although not yet FDA-approved for NPC, it has been approved for use in Europe for the treatment of NPC (49). Given that the length of the neurologically asymptomatic phase may be a major factor in determining the age of neurological onset and that disease progression after neurological involvement is linear (6), identification of affected patients before the onset of neurological symptoms is critical. The current diagnostic standard for NPC1 is an invasive skin biopsy and filipin staining in one of several specialized clinical laboratories worldwide (50). The lack of a noninvasive screening or diagnostic test contributes to a significant diagnostic delay, which has been shown to be 4.3 years in a predominantly pediatric cohort and 6.2 years in adults with NPC1 disease (6, 51). Recent advances in mass spectrometric detection of oxysterols raise the possibility that these cholesterol-derived biomarkers could be quantified with sufficient sensitivity to enable implementation of newborn screening (52, 53). A similar approach to detection of sterol compounds is being pursued for Smith-Lemli-Opitz syndrome, another inborn error of sterol metabolism (54). The finding that circulating oxysterols are informative with respect to NPC1 disease severity suggests that oxysterol biomarkers may also be useful for following disease progression or response to therapy by providing outcome measures in clinical trials. Validation of these oxysterol biomarkers is currently under way in an NIH-sponsored clinical trial (55).

MATERIALS AND METHODS

Animals

BALB/c NPC<sup>mut</sup> mice were obtained from Jackson Laboratories and maintained on a standard chow diet. Rotarod performance was monitored as described (15). Experimental procedures were approved by the Washington University Animal Studies Committee and conducted in accordance with the U.S. Department of Agriculture (USDA) Animal Welfare Act and the Public Health Service Policy for the Humane Care and Use of Laboratory Animals. NPC1 cats were raised in the animal colony of the School of Veterinary Medicine at the University of Pennsylvania under NIH and USDA guidelines for the care and use of animals in research (56). Treatment with 2-hydroxypropyl-β-cyclodextrin was performed as described previously (56). The experimental protocol was approved by the University of Pennsylvania Institutional Animal Care and Use Committee.

Human subjects

NPC1 fibroblasts and plasma were obtained from individuals enrolled in NIH protocol 06-CH-0186 (Evaluation of Biochemical Markers and Clinical Investigation of Niemann-Pick Disease, type C; principal investigator: F. D. Porter). This clinical protocol was approved by the National Institute of Child Health and Human Development Institutional Review Board, and the analysis of coded human samples was approved by the Human Studies Committee at Washington University. Plasma samples for diabetes and CAD subjects were obtained from a prospective registry (principal investigator: S. P. M.) for patients who have been admitted to St. Luke’s Hospital for in-hospital coronary angiography.

Cells

NPC1 mutant fibroblasts were obtained from skin biopsy specimens, and control human fibroblasts were obtained from the American Type Culture Collection (CRL-1474). Fibroblasts cell lines were cultured as described (57).

Oxysterol determinations

Plasma samples were collected in tubes containing K<sub>3</sub>-EDTA and BHT and stored at −80°C. CSF samples were collected using standard procedures in tubes containing BHT and stored at −80°C. Samples were analyzed in a blinded fashion. Before analysis, BHT (50 μg/ml) was added to plasma and CSF samples. For total oxysterol measurements, 200 pmol deuterated 27-HC (d<sub>5</sub>-27-HC) as an internal standard (IS) was added under a continuous argon stream, samples were saponified (room temperature for 2 hours), and chloroform-methanol extraction was performed twice as described (11, 58). All sample processing was performed under argon to prevent adventitious cholesterol oxidation. Oxysterol purification was accomplished using amino-propyl (Waters Sep-Pak Vac RC 500 mg NH<sub>2</sub> Cartridges) and silica columns (Isolute 100 mg Si 10 ml XL cartridges) (59). After solid-phase separation from other lipid species, oxysterols were derivatized using pyridine-hexamethyldisilazane-trimethylchlorosilane (3:2:1) (21), and analyzed by GC-MS using an Agilent Technologies 5975B inert XL MSD with an Agilent Technologies 6890N Network GC System. Oxysterols were monitored with ions at mass/charge ratio (m/z) 472 (7-KC), m/z 456 (3β,5α,6β-triol, 7α-HC, 7β-HC, 4β-HC, and 27-HC), m/z 413 (24(S)-HC), m/z 131 (25-HC), and m/z 461 (d<sub>5</sub>-27-HC). Quantitative GC-MS determinations were calculated from triplicate injections and from the linear response range of standard curves established for each oxysterol-IS pair. Recovery of oxysterol species in plasma samples was typically in the 60% to 70% range.

Cholesterol esterification

LDL-stimulated cholesterol esterification in fibroblasts was performed as described (60).

Cholesterol determinations

For fibroblasts, lipids were isolated from cells by extraction in hexane-isopropanol (3:2), and cellular protein was determined by bicineho-
ninic acid assay. Free cholesterol was quantified by GC-MS as previously described (61) and normalized to total cellular protein.

**Statistical analyses**

Results are expressed as mean ± SEM. For group comparisons, the statistical significance of differences in mean values was determined by a two-tailed single-factor analysis of variance (ANOVA) or Student's t test. To perform correlations, we analyzed the data using Pearson and Spearman correlations, as appropriate. A P value of ≤0.05 was considered significant. A Bonferroni posttest correction was used to adjust for multiple comparisons. For correlations with NPC1 disease severity, study subjects were ranked according to a disease severity scale from highest (most affected) to lowest (least affected) (6). For calculation of oxysterol ratios, 24(S)-HC values were first normalized to age-matched control values, which were interpolated from an exponential decay curve modeling the age-dependent decline in 24(S)-HC concentrations in control subjects (22).
